COVID-19 – does exercise prescription and maximal oxygen uptake ($VO_2$ max) have a role in risk-stratifying patients?

Author: Irfan Ahmed

As the UK shields ‘high risk’ patients and enforces social distancing measures, patients will be at risk of significantly reducing physical activity levels. We explore the evidence base for COVID-19-specific recommendations and exercise interventions to ‘precondition’ patients prior to infection and appraise the role of maximal oxygen uptake ($VO_2$ max) as a risk-stratifying triage tool. We conclude that structured exercise programmes can be used to maintain physical activity levels and prevent deconditioning and that $VO_2$ max has the potential to be used as a clinically relevant triage tool during the COVID-19 outbreak.

‘Exercise is medicine’

The current (COVID-19) pandemic has generated discussion about the impact of public health measures designed to protect critical care capacity across the NHS. We explore how aerobic testing can be adapted to ‘triage’ patients and help to allocate resources appropriately. With the crisis likely to continue for some time, we evaluate the role structured exercise programmes have in maintaining patients’ physical activity (PA) levels and explore the theory that exercise can be used to ‘precondition’ patients prior to infection.

How will public health measures impact patients’ physical activity levels?

The World Health Organization (WHO) has urged governments across the world to take immediate action and urgently ‘suppress transmission’ of the virus. While the UK undertakes practical measures to implement these recommendations and shield 1.5 million high risk patients at risk of severe illness and hospitalisation, the NHS will inevitably need to evaluate and minimise any potential negative impact this may have on patients’ health.

Author: ‘sport and exercise medicine registrar, The Royal London Hospital, London, UK’

One smart watch company has estimated that ‘social distancing’ measures have led to a 9% reduction in weekly PA levels across the UK as of 22 March, 2020. Patients who are self-isolating may be disproportionately affected by these measures, as PA has been shown to reduce the risk of disease-specific and all-cause mortality. In addition, exercise has been shown to be an effective treatment option in the control of long term conditions (LTCs) such as hypertension, diabetes and cardiovascular disease.

A study from the Hong Kong flu epidemic of 1997 demonstrated that patients who regularly performed ‘low/moderate exercise’ had a significantly lower risk of mortality than patients who ‘never/seldom’ exercised (odds ratio 0.62). Furthermore, murine studies indicate that moderate PA reduces susceptibility to respiratory infections and improved antiviral lymphocyte function. Based on this evidence, maintaining moderate PA will have an overall benefit to patients’ general physical health and may reduce the risk of contracting a respiratory infection.

What do we know about COVID-19 and high-risk patients?

Early data from the outbreak suggest that 80% of patients develop mild symptoms, 15% severe symptoms and 5% become critically ill. A case series of 138 hospitalised patients from Wuhan (China) has identified hypertension, diabetes and previous cardiovascular disease (CVD) as risk factors for intensive care admission. The median age of hospitalised patients was 51, compared to 66 for those admitted to intensive care. These case series suggest that discrete ‘high risk’ (age >65 and/or with pre-existing health conditions) COVID-19 populations exist, which are associated with a poorer prognosis and may have a disproportionate requirement for intensive care resources.

Given the high rates of mechanical ventilation and subsequent high mortality, it may be more appropriate to consider early community intervention and avoidance of hospital admission in this group. Previous community-based models in cardiovascular disease have proven to be cost-effective, reduce mortality and reduce unplanned hospital admissions. They also allow patients to maintain autonomy and be involved in active therapies that respect their preferred place of care.

Could exercise capacity help to triage patients and fairly allocate resources during the COVID-19 outbreak?

The current epidemiological models predict that the NHS is likely to face extended periods where demand for intensive care and
ventilators will far exceed capacity.\textsuperscript{11} The NHS will therefore need to find ways to rapidly ‘triage’ a large volume of patients, to ensure the greatest benefit for the largest number of patients. In a scenario where the NHS approaches peak capacity the decision to offer one patient a critical care bed may deny another patient that same opportunity.

If it is available, maximal oxygen uptake (VO\textsubscript{2 max}, measured in mL/kg/min) could be added to existing ‘triage’ criteria such as age and clinical background. While this idea is novel, and untested at scale, the current COVID-19 outbreak is challenging us to think of new ways to ensure just and equitable admission criteria. It would allow clinicians to make objective decisions on a case-by-case basis that takes into account patients’ biological age and premorbid condition.

What can we learn from perioperative care?

Cardiopulmonary exercise testing (CPET) for VO\textsubscript{2 max} is a routine part of preoperative assessment for some ‘high-risk’ surgical patients in the NHS. Previous studies have shown that disease-specific peak VO\textsubscript{2} cut-offs (such as <18.3 mL/kg/min for colorectal surgery) can be used to predict increased risk of 90-day mortality and risk of postoperative admission to high-dependency care.\textsuperscript{12}

Given the high prevalence of post-intensive-care syndrome (PICS),\textsuperscript{13} it is important to consider the baseline physical status of the patients prior to intervention.\textsuperscript{13} Certain risk factors – mechanical ventilation, age >65, admission >7 days and deconditioning – are associated with significant long-term disability and poor quality of life.\textsuperscript{11} Up to 25% of patients need help with activities of daily living one year after discharge and these patients are at increased risk of readmission to hospital.\textsuperscript{13}

At this early stage of the outbreak there are no studies to support the routine testing of VO\textsubscript{2 max} prior to infection with COVID-19, but it is likely to provide a global assessment of patients baseline physiological reserves. A low VO\textsubscript{2 max} could be used to identify patients who are unlikely to tolerate the physical demands of an intensive care admission and post-admission rehabilitation.

Can we physically precondition patients prior to infection?

The Centre of Perioperative Care has already issued expert guidance advocating for ‘brisk exercise’, smoking cessation, alcohol-free days and good nutrition as preventative measures in this outbreak.\textsuperscript{14} It is hoped that these simple measures will reduce the risk of patients requiring hospital admission, and potentially precondition ‘high risk’ patients prior to infection with COVID-19. We propose that even a small increase in baseline maximal oxygen uptake (VO\textsubscript{2 max}) across the population may have the effect of shifting a significant proportion of high-risk patients into a lower risk category.

Cardiac,\textsuperscript{15} pulmonary\textsuperscript{15} and preoperative\textsuperscript{16} home-based exercise programmes have been shown to be cost effective and significantly increase aerobic capacity in patients in a 4–6 week timeframe.\textsuperscript{14} The addition of strength-based programmes that incorporate balance and flexibility have also been shown to improve function and reduce the risk of falls in elderly patients.\textsuperscript{17} A balanced exercise programme will help to avoid deconditioning, improve the control of LTCs and help ‘high risk’ patients to maintain their independence.

There are currently no studies that evaluate the impact of preconditioning exercise interventions on COVID-19-specific mortality and morbidity. Given that 5% of patients become critically ill,\textsuperscript{8} it seems reasonable to assume that any baseline improvement in VO\textsubscript{2 max} is likely to confer benefit. We will however need further data to confirm this.

How could we practically test exercise capacity on a large scale?

There are a number of validated tests including the 6-minute walk test,\textsuperscript{18} activity monitors\textsuperscript{20} and the resting heart rate method\textsuperscript{20} that can be used to give an estimate of a patient’s VO\textsubscript{2 max}. All three methods can be performed remotely, be self administered\textsuperscript{19,20} or in the case of resting

| Table 1. Example of FIIT-VP exercise recommendation for patients regularly taking part in exercise with well-controlled hypertension.\textsuperscript{21} |
|---------------------------------------------------------------|---------------------------------------------------------------|---------------------------------------------------------------|
| **Aerobic training** |
| **Frequency** | 5–7 days/week |
| **Intensity** | Moderate (40–59% of VO\textsubscript{2} max) |
| This intensity will cause noticeable increases in heart rate and breathing but patient would still be able to maintain a conversation whilst exercising |
| **Type** | Prolonged activities using large muscle groups (eg walking, cycling, cross-trainer or rowing) |
| **Time** | Aim for >30 minutes a day. This can be accumulated continuously or in shorter 10-minute blocks |
| **Volume** | Aim for 150 mins/week |
| **Progression** | Patient can aim to start in 5–10-minute blocks with a 10% increase in weekly volume |
| **Strength training** |
| **Frequency** | 2–3 days/week (aim for non-consecutive days) |
| **Intensity** | Progress to start in keeping with patient’s baseline capacity |
| **Type** | Seated or bodyweight exercises can be used to start |
| **Time** | 2–4 sets of 8–12 repetitions |
| **Volume** | To include all major muscle groups |
| **Progression** | Gradual increase in load from body weight to 40–50% of 1RM and then 60–70% of 1RM |
| **Flexibility/balance training** |
| **Frequency** | 2–3 days/week (aim for non-consecutive days) |
| **Intensity** | Stretch to the point of feeling tightness or slight discomfort |
| **Type** | Seated exercises can be used to start |
| **Time** | Hold static stretch for 10–30s, 2–4 repetitions for each exercise |
| **Volume** | To include all major muscle groups |
| **Progression** | Gradual increase in range of motions and difficulty |

\textsuperscript{21}Adapted using recommendations from American College of Sports Medicine Guidelines for Exercise testing and prescription.\textsuperscript{19} 1RM – one repetition maximum, the maximum amount of weight that patient can possibly lift for one repetition.
heart rate be extracted from existing data in healthcare records. This would allow clinicians to remotely assess patients’ exercise capacity at home, without any additional burden in clinic time.

As we embrace new ways of working during the COVID-19 outbreak, the use of an app-based or streamed exercise programme may be a feasible and cost-effective way to deliver exercise interventions. The use of VO₂ max has many advantages as it is easy to collect and can be recorded in a patient’s summary care record, in a similar way to a list of past medical conditions. It may also be used to initiate advanced care plans for ‘high risk’ patients that take into account their wishes and outline appropriate levels of medical intervention.

**Formulating an exercise prescription**

In order to safely prescribe exercise, clinicians can use the ‘frequency, intensity, time, type, volume and progression’ (FIIT-VP) principle[1] (Table 1). Patients are advised to avoid extremes of temperature and include rest days. Expert opinion advises that patients displaying COVID-19 symptoms should rest for: ‘≤10 days from onset of symptoms plus 7 days from symptom resolution’. Adhering to a graduated exercise programme and not over-training (limiting training to 90 minutes per day) will reduce the risk of injury or compromising immunity.[11]

**Conclusion**

Maintaining physical activity levels during the COVID-19 outbreak will have significant physical health benefits to all patients. Further data will be needed to evaluate the role of exercise in ‘preconditioning’ patients prior to infection. Maximal oxygen uptake (VO₂ max), where available, has the potential to be used as part of existing ‘triage’ criteria to help risk stratify patients.[11]

**Key points**

- Physical activity will help provide general health benefits to all patients.
- Maximal oxygen uptake (VO₂ max) may prove to be a clinically relevant ‘triage’ tool in addition to age and clinical criteria.
- The role of exercise in preconditioning patients prior to COVID-19 infection is currently based on expert opinion.[11]
