How COVID-19 has changed the unselected medical take: an observational study

Authors: Kai Man Alexander Ho, Ananthi Anandhakrishnan, Arun Mahay, Yiwen Soo, Laurence B Lovat and Andrew P Rochford

Introduction
COVID-19 has had a profound effect on the NHS. Little information has been published as to how the unselected medical take has been affected.

Methods
We retrospectively reviewed patients who were referred to general medicine during March 2020. We compared clinical outcomes of patients with and without COVID-19.

Results
814 patients were included, comprising 777 unique patients. On average, 26 patients were admitted per day. 38% of admitted patients were suspected of COVID-19, with greater numbers of COVID-19 patients in the second half compared to the first half of the month (p<0.001). Logistic regression analyses showed suspected COVID-19 was an independent predictor for inpatient mortality (odds ratio [OR] = 6.09, p<0.001) and 30-day mortality (OR = 4.66, p<0.001).

Conclusions
COVID-19 patients had worse clinical outcomes and increased healthcare use compared to non-COVID-19 patients. Our study highlights some of the challenges in healthcare provision faced during this pandemic.

Statistical analyses

Data were collected using a Microsoft Excel spreadsheet over the month of May 2020 (Redmond WA, USA). Data analysis and statistical plots were produced using R: a Language and Environment for Statistical Computing software, version 4.0.2 (Vienna, Austria). Descriptive statistics with frequency and percentages were used for demographic data, admitting diagnosis and inpatient mortality. Median and interquartile range was used for age and length of stay. Differences between cohorts were analysed using the Mann-Witney U test for continuous, non-parametric variables and Chi-Squared test or Fisher’s Exact Test for categorical variables. We also performed univariate logistic regression modelling to identify individual factors associated with inpatient and 30-day mortality. Individual factors with a p-value ≤0.10 in univariate regression were entered into a multivariate logistic regression model to identify independent predictors of inpatient and 30-day mortality. Effect measures are presented as odds ratios (OR) and 95% confidence intervals (CI), with a p-value of ≤0.05 taken as significant, unless otherwise stated. Patients were analysed as intention to treat, hence if a non-COVID-19 patient subsequently tested positive for COVID-19, they remained in the non-COVID-19 cohort for analysis.

Results

In total there were 814 unselected medical admissions in March 2020. 37 patients were admitted twice in this period, meaning 777 individual patients were admitted overall. 58% of the patients were male.

Number of patients admitted

Fig 1 shows the number of admissions by day in March, as well as whether they were suspected to be COVID-19-related or not. The mean number of patients admitted per day was 26, with a standard deviation (SD) of 4.6. Similar numbers were admitted in the first half (1–15 March) of the month (mean 26; SD 4.42) compared to the second half of the month (mean 26.5; SD 4.93). The lowest number of patients admitted on a single day was 21 March, where 14 patients were admitted. Except for this day, the admission numbers on all other days were within 2 SD of the mean. Although 21 March was a Saturday, no clear weekend effect of reduced admission numbers could be seen in our data.

The first suspected COVID-19 related admission occurred on 10 March, when three patients were admitted. The highest number recorded was 27 on the 30 March. In contrast, 4 March saw the highest number of non-COVID-19 patients admitted (34), although this decreased to single figures in the last week of March, with only four non-COVID-19 patients admitted on 29 March. Moreover, there was a gradual increase in the proportion of patients with COVID-19 as March wore on, with a decrease in non-COVID-19 patients. There was a significant difference in the proportion of COVID-19 and non-COVID-19 patients between the 1–15 March ($\chi^2 = 279.98$, df = 1, p < 0.001).

Admitting diagnosis

Fig 2 shows the specialty relating to the admitting diagnosis during the month of March. 307 (38%) patients were admitted with suspected COVID-19. The other major admitting diagnoses fell under cardiology (102; 13%), non-COVID-19 respiratory (95; 12%), gastroenterology (82; 10%) and geriatrics (78, 9.6%).

Comparison between suspected COVID-19 and non-COVID-19 outcomes

Table 1 summarises the demographics and clinical outcomes of suspected COVID-19 and non-COVID-19 patients. Suspected COVID-19 patients were more likely to be older (p=0.004), be
male (p<0.001) and of Black or Other ethnicity rather than White (overall p<0.001). 194/307 (63%) patients who were admitted with suspected COVID-19 ended up with a positive admission SARS-CoV-2 swab test. In addition, we identified 18 patients who were admitted for non-COVID-19 reasons but subsequently tested positive for SARS-CoV-2 in hospital. Suspected COVID-19 patients were more likely to be diabetic (p=0.001) and/or hypertensive (p=0.003) but less likely to have a smoking history (p=0.002). Broadly speaking, patients admitted with COVID-19 had worse clinical outcomes compared to patients admitted with a non-COVID-19 diagnosis. This included a higher median length of stay (p<0.001), a higher inpatient and 30-day mortality (both p<0.001) as well as a greater requirement for non-invasive ventilation and intubation (both p<0.001).

Univariate logistic regression analysis was initially used to select patient factors associated with inpatient and 30-day mortality (see supplementary material S1). Subsequently, multivariate logistic regression analysis was carried out to assess the effect of age, gender, suspected COVID-19 status, diabetes mellitus, hypertension, chronic kidney disease and smoking history on mortality (see supplementary material S2). Increasing age and suspected COVID-19 status were both independent predictors for inpatient mortality, although the effect was stronger for suspected COVID-19 (suspected COVID-19: OR 6.09, 95% CI 3.78–10.1; age: OR 1.07, 95% CI 1.05–1.08). A similar pattern was also noted for 30-day mortality (suspected COVID-19: OR 4.66, 95% CI 2.99–7.38; age: OR 1.06, 95% CI 1.05–1.08).

Comparison between positive and negative SARS-CoV-2 patients swab test results in suspected COVID-19 patients

We were also interested in investigating whether there were differing clinical outcomes between suspected COVID-19 patients who subsequently had a positive and a negative SARS-CoV-2 swab test (see supplementary material S3). Notably, 25 patients (22%) who tested negative on admission subsequently had a positive SARS-CoV-2 swab test as an inpatient, although only 50/113 patients (44%) underwent further testing. Our data show that there was a significant difference in median length of stay (6 days compared to 4 days, p=0.006) and those remaining as inpatient (4 patients compared to 1 patient, p=0.031). Patients testing positive also were more likely to be intubated (16% compared to 9%, p=0.04) and be hypertensive (64% compared to 50%, p=0.019).

Discussion

We believe our study is the first to specifically investigate the effect of the COVID-19 pandemic on the unselected medical take in an NHS hospital. Perhaps surprisingly, our data demonstrate that the number of admissions during the month of March remained constant. However, the proportion of patients admitted with COVID-19 increased dramatically towards the end of March. This was compensated by a decrease in patients being admitted onto the medical take with other conditions. There have been several reports of altered health behaviour during the month of March, such as reduction in emergency department attendances, reduction in emergency hospital admissions and doubling of calls to NHS 111. A study demonstrated a 40% fall in patients admitted for acute coronary syndrome from mid-February to late-March 2020, with a greater decline for non-ST elevation myocardial infarctions (NSTEMI) compared to STEMI. In contrast, a report suggested no change to ambulance demand for both myocardial infarctions or cerebrovascular disease. It is likely that even though there may have been a drop in absolute numbers attending the hospital, a higher proportion of patients requiring hospitalisation counterbalanced the trend.
Our data suggest firstly that comorbidities such as diabetes mellitus and hypertension were more common in COVID-19 compared to non-COVID-19 patients, although we found that a smoking history was more common in non-COVID-19 patients. Furthermore, there were worse clinical outcomes for patients admitted with COVID-19 compared to non-COVID-19 patients. Our multivariate logistic regression modelling suggested statistically significant associations in predicting inpatient and 30-day mortality, even when the effects of age, gender and comorbidities were factored in. Our findings are broadly in line with several larger studies which have been published looking at outcomes of COVID-19 patients in hospital. A UK multicentre series of 20,133 patients found that the median age of admission was 73 and 60% of patients were male. Increasing age, male gender, diabetes, hypertension, cardiovascular disease and chronic respiratory disease were all associated with worse outcomes. The mortality rate was 26%, although 34% were still inpatient at time of reporting. 16% were treated with non-invasive ventilation, and 10% were intubated. Meanwhile an American study had an intubation rate of 12% and mortality rate of 21%, while a Chinese study had 14% of patients treated with non-invasive ventilation, an intubation rate of 17% and a mortality rate of 28%. One stark contrast is that compared to the UK series, despite a younger cohort in our population, there was a similar mortality rate. Notably, it has been reported that the London Borough of Newham recorded the highest COVID-19 mortality rate in England and Wales. While it is entirely possible that nosocomial spread may be a factor, it is more likely that false negative tests were the culprit. A preprint testing positive for SARS-CoV-2 had a higher median length of stay, and research to our hospital.

FET = Fisher’s exact test; IQR = interquartile range; LOS = length of stay; MWUT = Mann-Whitney U test.
systematic review consisting of five studies showed false negative rates of 2% to 29% for the SARS-CoV-2 RT-PCR test, although there was considerable heterogeneity in sensitivity estimates.\(^{18,19}\) A sensitivity of 70% for a SARS-CoV-2 RT-PCR test is felt to be a reasonable estimate, given at present there is no clear reference standard which RT-PCR tests are measured against.\(^{18}\) This therefore demonstrates the need to not be over-reliant on initial swab test results, take a repeat sample and to treat clinically if COVID-19 is suspected.

### Study limitations

This was a single centre retrospective observational study and hence may not be representative of the wider UK population. Secondly, we did not investigate all confounders which may influence clinical outcomes, such as cardiovascular disease. Our study also excluded patients who were seen by the emergency department and then discharged, hence only more serious cases of COVID-19 requiring hospitalisation were included in our dataset. There is a delay in recording out of hospital mortality on the hospital systems; our quoted mortality figures may therefore underestimate the true mortality figure.

### Conclusions

Our study highlights how the unselected medical take in our hospital has changed during March 2020 as the COVID-19 pandemic progressed. Patients admitted with COVID-19 typically suffered worse clinical outcomes compared with patients admitted for non-COVID-19 reasons, with greater healthcare demands. It serves as a reminder as to how severe COVID-19 can be for the individual patient, and the need for vigilance if and when COVID-19 cases rise again due to a second peak.

### Supplementary material

Additional supplementary material may be found in the online version of this article at www.rcpjournals.org/clinmedicine:

S1 – Univariate logistic regression analysis of baseline and clinical characteristics associated with inpatient and 30-day mortality.

S2 – Multivariate logistic regression of baseline and clinical characteristics associated with inpatient and 30-day mortality.

S3 – Subgroup analyses of all suspected COVID-19 patients and their admission SARS-CoV-2 RT-PCR swab test results.

### Acknowledgements

The authors would like to thank Xosé Couto Parada, chief healthcare scientist in virology at Bart’s Health NHS Trust for assistance with the technical aspects of the SARS-CoV-2 PCR assay.
