Infections in people who inject drugs on the acute medical take

Authors: Anna Crepet\textsuperscript{A} and Catherine Sargent\textsuperscript{B}

People who inject drugs are disproportionately affected by acute/chronic bacterial and viral infections that are a cause of significant morbidity. Clinical presentations to the acute medical take vary from skin and soft tissue infections to complications of bacteraemias, and can be challenging with difficulties in adherence, pain management, early self-discharges and loss to follow-up. This review summarises the most recent UK epidemiology of injecting drug use and infection as well as clinical presentation and management.

Introduction

People who inject drugs (PWID) are vulnerable to a wide range of viral and bacterial infections with significant morbidity and mortality.

Psychoactive substances that can be injected are heroin, cocaine, methamphetamine, ketamine and fentanyl. Polysubstance use is common. Injecting psychoactive substances often takes the course of a chronic, relapsing disease such as diabetes or cardiovascular disease.

Epidemiology

According to the \textit{World Drug Report 2021}, 35 million people are estimated to be suffering from drug use disorders.\textsuperscript{1} Around 1.2\% of global population used opioids for non-medical purposes with the highest prevalence in North America (3.6\%).\textsuperscript{1}

The UK has 0.82\% of the adult population who are high-risk opioid users: the highest prevalence in Europe.\textsuperscript{1} Heroin (94\%) and cocaine (58\%) are the most injected psychoactive drugs in the UK.\textsuperscript{2}

In an anonymous survey in 2020, 65\% of PWID had a history of imprisonment; 49\% had been homeless in the previous year; 16\% had ever traded sex for money, goods or drugs; 43\% had indirect sharing of needles, syringes, mixing containers or filters; and 24\% had direct sharing of needles and syringes.\textsuperscript{2}

Systematic reviews have shown mortality rates that are 10–15 times higher than in the general population with significantly lower life expectancy in PWID. The most common causes of death were drug poisoning followed by chronic obstructive pulmonary disease and suicide.\textsuperscript{3}

Morbidity is due to sharing of injecting equipment with risk of blood-borne virus acquisition, contaminated injecting sites resulting in skin and soft tissue infections (SSTIs), vascular complications from thromboembolism to amputation, and systemic infections (eg infective endocarditis (IE); Fig 1).\textsuperscript{4,5}

In 2020, a UK survey found that 20\% of PWID had chronic hepatitis C (HCV) infection, 12\% had hepatitis B (HBV) and 1.1\% had HIV.\textsuperscript{6} The pandemic has resulted in decreased uptake of the HBV vaccine and missed opportunities for diagnosis persist. It has also challenged continuity of care in drug and alcohol services, with effects that are slowly becoming visible.\textsuperscript{6}

Key points

People who inject drugs are a group who may have physical and/or mental health issues as well as social vulnerabilities; all putting them at risk of a wide range of infections with significant morbidity and mortality.

Common infections are due to blood-borne viruses (mainly hepatitis C), skin and soft tissue infections, and deep-seated bacterial infections.

Substance use disorder often takes the course of a relapsing and remitting disease that needs a multidisciplinary, non-judgemental approach, linking inpatient care with community care.

It is important to talk about injection practice to understand risk factors and explore prevention measures.

Prescribing opioid substitution therapy is an evidence-based intervention to reduce morbidity and mortality, it can also facilitate adherence to medical care and reduce infectious risks.

Severe bacterial infections disproportionately affect PWID. Group A Streptococcus (GAS) and Staphylococcus aureus (methicillin-sensitive and -resistant (MSSA and MRSA, respectively)) infections have been increasing in the UK since 2013. The reason is not clear, but several factors have been postulated including homelessness, poor hygiene, and injecting in the groin and other high-risk sites. In 2020, 7% of all invasive GAS isolates, 19% of MRSA and 11% of MSSA bacteraemia in the UK were associated with injecting drug use. Information on risk factors was missing in many cases so this is likely an underestimate.6,7

Increased SSTIs are related to the drug itself (black tar heroin and speedball (a combination of heroin and cocaine)), injection practices (eg skin-popping (subcutaneous or intramuscular use), frequency of use per needle, injection frequency and inguinal injection as opposed to antecubital injection), needle-licking (a practice aimed at cleaning, enjoying the taste and avoiding drug wastage) and necrosis secondary to excipients (eg citrate and levamisole).8,9,9

In 2020, a survey found 38% of PWID had symptoms of an injection site infection during the preceding year.4 Of these, 55% did not seek healthcare treatment.7 A study of 445 PWID in London found that 46% did self-care for their worst SSTI and 43% waited for more than 10 days before seeking medical care or did not seek it at all, which is a concern for potentially more severe infections and complications.10

PWID have a higher risk of IE due to the direct inoculation of bacteria into the bloodstream and direct mechanical damage due to impurities present in injected drugs. In an international cohort of 7,616 patients with IE, the 591 PWID were much younger patients and had higher rates of systemic emboli.11

Poor oral health with dental caries, tooth erosions/loss and periodontal disease is commonplace in PWID and can be a risk factor for invasive bacterial infections. Multiple predisposing factors include alcohol and tobacco use, heroin use (which itself causes xerostomia), high sugar-containing methadone use, poor nutrition, and infrequent dental follow-up.12

The most common microbiological organisms associated with intravenous substance use are MSSA, MRSA and GAS, which are part of the normal skin flora. Organisms that are a part of the normal oral flora (such as viridans streptococci, Eikenella corrodens and Candida species) have been isolated. They can all cause wound-related and systemic infections. Polymicrobial infections have also been described.

In the USA, candidaemia rates have been increasing among PWID, on a background of historical descriptions of outbreaks related to contaminated lemon juice used in the preparation of the injected drug.13 Sporadic outbreaks of tetanus, botulism and anthrax are also ongoing in this population and likely due to contamination of the drug, diluents and excipients with spores.6

The prevalence of tuberculosis in PWID is higher than in the general population. They are more likely to have pulmonary involvement and PWID have higher risk overall of severe outcomes (critical care / death) compared with the general population, partially due to the high prevalence of chronic diseases.14

Presentation and diagnosis

Assessment of patients’ injection practices gives the opportunity to understand risks and facilitate discussions on prevention. This includes how often they share needles and injection equipment with others; how much they re-use needles, cookers and filters; which water they use; and if they rotate sites and disinfect skin before every use.7

The most common SSTIs are cellulitis, abscesses, ulcers, necrotising fasciitis and thrombophlebitis. These are a result of local trauma to the skin, the direct inoculation of bacterial skin flora, sharing of unsterile equipment, using contaminated drugs or the local effects of the injected drugs themselves (tissue necrosis).9

Long-term complications of SSTIs are chronic venous disease and ulcers; repeated femoral injections can cause deep venous thrombosis, sinus formation and pseudoaneurysms. Septic arthritis and osteomyelitis are common complications acquired via haematogenous or contiguous spread. Severe systemic sepsis, bacteremia and IE can develop further to complications such as spondylodiscitis and epidural abscess, deep seated infection in any organ, musculoskeletal abscesses, septic pulmonary emboli, endophthalmitis etc.

Investigations

Based on the history, risks and thorough clinical examination (including inspection of injection sites), essential investigations should include blood cultures, wound swabs, tissue or fluid for microbiological investigations, and serology for HIV, HBV and HCV.

The following should be considered: pregnancy testing; sexual health screening (syphilis, chlamydia, gonorrhoea and Mycoplasma); drug testing on saliva, blood or urine; and imaging as required (Table 1).15

Treatment

There is very limited literature for treatment of bacterial infections in PWID. These patients are usually younger, have fewer comorbidities and have more mental health issues, which affects adherence to medical treatment. A multidisciplinary approach and a supportive network in hospital in conjunction with the community is key. Flexibility from medical staff and setting achievable goals with patients can reduce the risk of early self-discharge or loss to follow-up.

Opioid substitution therapy with methadone or buprenorphine is an evidence-based intervention to reduce use, cravings and death. In-hospital initiation or continuation is an important action to improve compliance and reduce risk of blood-borne virus acquisition and recurrent injection-related SSTIs.

The long course of antimicrobial treatment necessary for IE, osteomyelitis or septic arthritis is often difficult to adhere to in unstable social circumstances. Two large trials, OVIVA and POET, have shown non-inferiority of oral versus intravenous antibiotics, but had very few PWID in the study groups. The use of long-acting lipoglycopeptides (dalbavancin) licensed for SSTIs has been increasingly used off label for bone/joint infections and bacteraemia, as they reduce inpatient stay. Outpatient parenteral antibiotics are rarely given due to issues with indwelling line care and the risk of overdose or reinfection.

Source control with surgery or interventional radiology for SSTIs and deep collections should always be considered. Cardiac surgery for IE has been associated with improved survival but tend to be less frequently performed given concerns about follow-up.

Management of acute pain can be paramount; for example, in cases of deep abscesses or spondylodiscitis. Poor acute pain management can result in self-discharge, self-medication, sedation and overdose, especially when tolerance to opioids is uncertain and when patients are using additional centrally active medications.

Methadone and buprenorphine are prescribed once daily as treatment for substance use disorders but the analgesic effect lasts only 6–8 hours. The Faculty of Pain Medicine recommends continuation of the baseline opioid but splitting the dose into two or three times a day and titrating additional analgesia to effect, with multimodal non-opioid analgesic strategies followed by incremental doses of opioids. Non-opioid analgesics that can be useful are non-steroidal anti-inflammatory drugs, ketamine, lidocaine, glucocorticoids and gabapentinoids. Opioid cross-tolerance may be present so that PWID typically require higher doses of opioids than naive patients. Initially, regular short-acting opioids need to be promptly up-titrated and then tapered after the acute pain phase.

</tbody>
</table>

Opioid substitution therapy can interact with many pharmaceutical agents (including antimicrobial agents) as methadone and buprenorphine are both metabolised by cytochrome P450 (Table 2).22

Prevention and patient education

The inpatient stay may provide a suitable opportunity to vaccinate a patient or encourage to engage in vaccination or treatment programmes (eg hepatitis C treatment; Table 1).6

In a survey among healthcare providers in the USA, 59% reported being uncomfortable or neutral in educating PWID about reducing risk of infection during the injection process. More than half reported no or low knowledge of harm reduction strategies. The educational toolkit by Harvey et al helps address this effectively (Table 3; Fig 1).5
